Background: Hostility and anger are risk factors for, or co-occur with, many health problems of older adults such as cardiovascular diseases, all-cause mortality, and asthma. Evidence that negative emotions are associated with chronic airways obstruction suggests a possible role for hostility in the maintenance and decline of pulmonary function. This study tests the hypothesis that hostility contributes to a faster rate of decline in lung function in older adults.

Methods: A prospective examination was undertaken of the effect of hostility on change in lung function over time. Data are from the VA Normative Aging Study, an ongoing cohort of older men. Hostility was measured in 1986 in 670 men who also had an average of three pulmonary function examinations obtained over an average of 8.2 years of follow up. Hostility was ascertained using the 50-item MMPI based Cook-Medley Hostility Scale. Pulmonary function was assessed using spirometric tests to obtain measures of forced expiratory volume in 1 second (FEV₁) and forced vital capacity (FVC).

Results: Baseline pulmonary function differed between high and medium/low hostility groups (mean (SE) percent predicted FEV₁ 88.9 (18.5) v 95.3 (16.9) and FVC 92.5 (16.5) v 98.9 (15.9), respectively; $p < 0.01$ for both). This overall association between higher hostility and reduced lung function remained significant after adjusting for smoking and education, although the effect size was attenuated for both FEV₁ and FVC. Higher hostility was associated with a more rapid decline in lung function, and this effect was unchanged and remained significant for FEV₁ in multivariate models but was attenuated for FVC. Each standard deviation increase in hostility was associated with a loss in FEV₁ of approximately 9 ml/year.

Conclusions: This study is one of the first to show prospectively that hostility is associated with poorer pulmonary function and more rapid rates of decline among older men.

Despite evidence that emotions are associated with chronic airways obstruction, little work has been undertaken on the role of psychological factors in the growth and decline of pulmonary function.^{1,2} Variability in pulmonary function with aging is significant and reflects factors that influence both the development of healthy lung function and the rate of decline. Accelerated rates of pulmonary function decline are associated with increased risk for a variety of poor health outcomes, including premature mortality.^{3–6} Epidemiological studies have suggested that smoking, occupational exposures, familial factors (genetic or possibly prenatal influences), childhood illnesses, and air pollution play a role in both lung growth and development and pulmonary function decline. These factors, however, account for a relatively small proportion of risk, suggesting that as yet unidentified risk factors need to be further explored. Hostility and anger are considered to be risk factors for, or to co-occur with, many health problems of older adults such as cardiovascular diseases, all-cause mortality, and altered immune system function,^{7–9} although studies have not found uniformly positive associations with these outcomes.¹⁰ Evidence that emotions are associated with inflammatory processes¹¹ as well as chronic airways obstruction¹² suggests a possible role for psychological factors in the growth and decline of pulmonary function. However, the possible role of hostility in shaping patterns of change in pulmonary function has not been explored.

Several studies have linked short term changes in mood with transitory changes in lung function.^{13,14} In an examination of lung function over a longer period of time, we have shown that pessimism is related to lower levels of forced expiratory volume in 1 second (FEV₁) and forced vital capacity (FVC) and prospectively related to accelerated rate

of lung function decline among older men.² Some studies have identified an inverse association between negative emotions and pulmonary function in people with pre-existing respiratory diseases such as asthma¹⁵ or chronic obstructive pulmonary disease (COPD).¹⁶ One recent study reported that hostility was consistently associated with reduced pulmonary function using a cross-sectional design in a sample of young adults.¹⁷ However, we know of no published research that has examined the prospective association of hostility with decline in pulmonary function. The present study seeks to address this gap and tests the hypothesis that hostility contributes to faster rates of decline in lung function among older adults, controlling for covariates known to be associated with lung function and also linked to hostility or negative emotion.

METHODS

The Normative Aging Study (NAS) is a longitudinal study of aging established by the Veterans Administration (VA) in 1961.¹⁸ The study cohort consists of 2280 predominantly white community dwelling men from the Greater Boston area aged 21–80 years at the time of entry. Volunteers were screened at entry according to specific health criteria,¹⁸ and those with chronic health conditions including asthma, chronic bronchitis, and chronic sinusitis were excluded. The study protocol was approved by the Human Studies Subcommittee of the Department of Veterans Affairs Medical Center and informed consent was obtained from all subjects.

Abbreviations: BMI, body mass index; FEV₁, forced expiratory volume in 1 second; FVC, forced vital capacity; HPA, hypothalamic-pituitary-adrenal; SNS, sympathetic nervous system

Assessment of hostility

Hostility was assessed using the 50-item MMPI based Cook-Medley Hostility Scale (Ho)¹⁹ taken from Form AX of the MMPI.²⁰ Items assess suspiciousness, resentment, and cynical mistrust, and respondents rated each item as either true or false. Prior research has suggested that the scale demonstrates good validity²¹ and reliability, with cross-time correlations highly stable in individuals aged over 40.²² Internal consistency reliability of the scale in the present sample was 0.7. Hostility scores were analysed as a continuous variable with higher scores on the scale indicative of higher hostility levels. For some analyses we also categorised hostility score into tertiles (high, moderate, low) based on the distribution of scores in this cohort.

Form AX of the MMPI, which includes items from both the MMPI and the MMPI-2, was administered by mail to all active cohort members (n = 1881) in 1986.²⁰ 1550 men responded (82.4% response rate), of whom 1472 provided complete and valid questionnaire data (95% of those responding). Comparison of men included in the study with those excluded (based on whether they completed the questionnaire) indicated that the non-responders were somewhat younger and more likely to be current smokers, but did not differ on level of education or pulmonary function. Men were included in the present study if they had a pulmonary examination within 1 year of completing the MMPI and at least one follow up examination. This resulted in a study population of 670 men.

Measurement of other risk factors for pulmonary function impairment

Every 3–5 years, participants in the NAS were seen for a comprehensive examination that included a medical history and physical examination, electrocardiogram, chest radiograph, blood and urine tests, and spirometry. Before the examination participants were instructed to refrain from eating or drinking after midnight and to refrain from smoking after 20.00 hours on the previous night. Cigarette smoking status (current, former, never) was ascertained by a trained interviewer. Current smokers were defined as men who smoked ≥ 1 cigarette per day. Weight and height were measured with participants wearing only socks and underpants, from which body mass index (weight/height²) is calculated. Participants also reported whether they had completed education beyond high school (yes/no).

Assessment of pulmonary function

At baseline, this study included measures of pulmonary function obtained within 1 year of the 1986 survey. Included subjects were followed for a mean (SD) of 8.22 (1.98) years. The mean number of spirometric tests was 3.5 (range 2–4). FVC manoeuvres were performed in the standing position without a noseclip using an 8 litre water-filled spirometer (Warren E Collins Inc, Braintree, MA, USA). Acceptability of the spirometric tests was judged according to American Thoracic Society standards.²³ Up to eight spirometric tests were performed until at least three acceptable tests were obtained from each subject, of which at least two were reproducible (FEV₁ and FVC within 5%). Predicted values for FEV₁ and FVC were calculated using regression equations relating each spirometric index to age and height among 215 asymptomatic lifetime non-smokers in the NAS cohort.

Data analysis

Data were examined using hierarchical linear modelling (HLM; also known as random effects modelling) using repeated measures analysis in the Statistical Analysis System (PROC MIXED; SAS).²⁴ We estimated parameters for the effect of hostility on pulmonary function over time, using

continuous variables for both indices. HLM techniques are appropriate for examining both individual time paths (change in pulmonary function over time) and whether the amount of change over time varies depending on a fixed effect (level of hostility).²⁵ Multiple observations at different times are formally viewed as nested within the individual. After variance in individual intercepts and slopes has been examined, a conditional model predicts intercept and slope terms using group as a predictor variable. In these models, individuals do not need to have the same number of observations from which to calculate change over time. Using this method, we can account for the correlation between levels of pulmonary function measured in the same individual across examinations, baseline pulmonary function levels, and also control for effects of smoking and other potential confounders.²⁵ The covariance structure for the pulmonary function data was specified using a compound symmetry model, a structure that specifies constant variance and covariance which was found to be the best fit.

As we were primarily interested in the “between group” effects (comparing more versus less hostile people), we present data only for fixed effects. To determine whether hostility influenced the rate of decline in pulmonary function we created interaction terms for hostility and time (all variables were centred). Parameter estimates represented by these interaction terms may be interpreted as the change in pulmonary function (ml) per standard deviation change in hostility per year. Because change in pulmonary function was not normally distributed, we also ran analyses using log transformed FEV₁ and FVC scores. Findings with these analyses were largely similar but significantly stronger than those based on analyses with raw FEV₁ and FVC scores. However, for ease of interpretation and following previous studies using this analytical method,^{26, 27} we report the results using raw scores. To simplify presentation in the figures, we initially divided the sample into tertiles based on the distribution of hostility scores. Examination of effects using ANOVA techniques testing differences across groups showed that trends for moderate and low hostility were similar, with pulmonary function in both groups generally significantly different from the high hostility group but not from each other. For parsimony, we combined the low and moderate

Table 1 Distribution of pulmonary function risk factors and pulmonary function (ml) according to level of hostility at baseline

Risk factor	High hostility (n = 214)	Medium/low hostility (n = 455)

groups and present results using a dichotomised hostility score (using cut points 7–20 and 20.2–37).

RESULTS

The mean (SD) age of the sample at baseline was 62.0 (6.9) years (range 45–86). The mean (SD) hostility score was 18.5 (5.0) (range 7–37), and the distribution was somewhat skewed toward lower hostility scores. We examined the relationship between risk factors for pulmonary function impairment and hostility for the full sample at baseline. As shown in table 1, age, height, smoking status, and education did not significantly vary according to hostility level, as indicated by *t* tests (age, height) and χ^2 analyses (smoking status, education). Although not significant, more hostile men appeared somewhat more likely to be ever smokers. We also examined the association between hostility and mean FEV₁ and FVC at each examination, controlling for age and height, using analysis of covariance (table 1). While percentage predicted values of FEV₁ and FVC were in the normal range at all levels of hostility, more hostile men had significantly lower levels of FEV₁ and FVC than less hostile men at baseline and every other examination over the follow up period.

We also examined whether hostility was related to the punctuality of the medical assessment to determine whether less hostile men came in sooner for their physical examination than more hostile men. If this was true, such differences might influence any differences seen in pulmonary function. We found no relationship between punctuality of medical assessment and hostility, and therefore did not include it as a variable in subsequent analyses.

Standard control variables including age, height, education, and smoking status were adjusted for in the hierarchical linear models. The mixed regression models indicated a strong main effect for hostility (tables 2 and 3). There was an inverse association between the hostility score and pulmonary function, suggesting that more hostile men had significantly lower levels of FEV₁ ($b = -102.41$, standard error (SE) = 20.71, $p < 0.001$) and FVC ($b = 126.14$, SE = 22.98, $p < 0.001$) when age, height, and time between assessment of hostility and each pulmonary examination (years of follow up) were adjusted for (model 1, tables 2 and 3). Parameter estimates were somewhat attenuated but remained significant after adding smoking status and education to the models (model 2, tables 2 and 3). Age, height, years of follow up, education, and smoking were all significantly related to both FEV₁ and FVC in the expected directions.

Our primary research question concerned whether the rate of decline in pulmonary function was faster for more hostile

than for less hostile men. Using an interaction term with hostility and time, we were able to test formally whether the rate of decline depended on the hostility level. In the base model, controlling for age, height, and time to examination, a significant interaction term ($b = -9.08$, SE = 3.49, $p < 0.01$) suggested that more hostile individuals experienced a faster rate of decline in FEV₁ than less hostile individuals, and this finding remained strong after adjustment for smoking and education level (table 2). This represents a decrease of approximately 9 ml per year in FEV₁ with each standard deviation increase in hostility. The effects were similar but slightly attenuated for FVC. In the base model, the interaction term ($b = -7.98$, SE = 4.89, $p = 0.10$) suggested that hostile individuals experienced a somewhat faster rate of decline in FVC than less hostile individuals, although the effect was further attenuated after adjustment for smoking and education level (table 3).

To understand the interaction terms more clearly, we used the dichotomised (low/medium versus high) hostility scores to examine rates of decline among men with high levels compared with those with moderate or lower levels of hostility (assuming equal lung function at the outset). Figure 1 shows that greater hostility was associated with a faster decline in FEV₁. The findings for FVC were similar but attenuated (fig 2). These analyses suggest that more hostile people have lower levels of lung function at the outset, and also a faster rate of decline in lung function over time relative to their less hostile counterparts. For example, the decline in FEV₁ in hostile individuals was approximately 37 ml/year compared with 32 ml/year in less hostile individuals. This difference in rate of decline is comparable to that found between male current smokers and never smokers in other studies, with differences of 5–7 ml/year.²⁶ The results for FVC were similar but of a smaller magnitude.

A number of potential confounders that need to be considered in the relationship between hostility and lung function and lung function decline, including body mass index (BMI), smoking dose, presence of coronary heart disease (CHD), and pessimism—a risk factor for lung function decline identified in earlier work with this sample.^[2] We consider each of these potential confounders, but do not show results when the findings are not substantially changed from those reported above. Men with more hostility also had higher BMI (mean (SD) 27.27 (3.31) kg/m²) than those with low/medium hostility (26.49 (3.17) kg/m², t (668) = -2.91, $p = 0.004$). However, when BMI was included as a covariate, the results for the association between hostility and lung function were only slightly attenuated; all independent effects that were seen in the original models

were maintained. Similarly, we considered the possibility of residual confounding in models that controlled only for smoking status without taking account of dose. Although individuals with high hostility were somewhat more likely to smoke more (mean 24.3 pack years) than medium/low hostile individuals (mean 22.3 pack years), this difference was not significant ($t(668) = -0.81$, $p = 0.41$). Moreover, in models controlling for pack years instead of smoking status, associations between hostility and lung function were unchanged. After adjusting for effects of smoking dose on rate of decline over time for both FEV₁ and FVC, an inverse association between hostility score and pulmonary function was maintained (FEV₁: $b = -88.56$, $SE = 20.31$, $p < 0.0001$; FVC: $b = -113.31$, $SE = 22.99$, $p < 0.0001$); the rate of decline in pulmonary function was still faster for more hostile men with regard to FEV₁ ($b = -8.49$, $SE = 3.52$, $p = 0.02$) but effects were attenuated for FVC ($b = -6.33$, $SE = 4.95$, $p = 0.20$). In stratified analyses, the effects of hostility on the rate of decline in lung function were similar in direction to the original findings, with some differences in the magnitude of effects. Hostility was inversely associated with FEV₁ and FVC in both never and ever smokers, but in never smokers the associations were not significant. However, the effects of hostility on decline in lung function were strong in never smokers (FEV₁: $b = -12.95$, $SE = 6.28$, $p = 0.04$; FVC: $b = -22.21$, $SE = 8.85$, $p = 0.01$) despite the significantly reduced sample size ($n = 246$); in ever smokers the effects were still clearly evident for FEV₁ ($b = -7.93$, $SE = 4.25$,

$p = 0.06$) but were highly attenuated for FVC ($b = -0.89$, $SE = 5.94$, $p = 0.88$). Finally, the effects of hostility on lung function were also unchanged when men with CHD diagnosed in 1986 were excluded from the analyses or when models included pessimism as a covariate.

DISCUSSION

To our knowledge these prospective findings are the first to demonstrate an association between hostility and rate of decline in pulmonary function, an effect that was consistent for FEV₁ and FVC and independent of smoking status. Higher levels of hostility were associated with both lower levels of pulmonary function at baseline and also with a faster rate of decline in lung function over time. It is interesting to note that, among more hostile men, pulmonary function was worse at every examination over a 10 year period than in less hostile men.

While it is possible that higher levels of pulmonary function lead to lower levels of hostility, several factors argue against this explanation. Firstly, the longitudinal finding of an effect of hostility on rate of decline after taking account of initial levels of pulmonary function suggests that hostility influences changes in lung function rather than vice versa. In addition, the levels of lung function were in the normal range at the outset of the study, making it less likely that poor lung function could lead to hostility. Although we measured hostility at only a single time point, the Cook-Medley Hostility Scale was designed as a trait measure and, among older adults, levels tend to be relatively unchanging over a long span of time.²² It could be that there is a third

**Figure 1** Effect of hostility on forced expiratory volume in 1 second (FEV₁) over time.**Figure 2** Effect of hostility on forced vital capacity (FVC) over time.

factor leading to hostility, low pulmonary function, and faster rates of pulmonary function decline. While the current analyses were able to control for some plausible third factors such as age or socioeconomic status, others are possible.

The findings of this study are consistent with other work that has found negative cognitions, emotions, and behaviours to be associated with poorer and more rapid decline in lung function.²⁻¹⁷ Chronic lung problems and diseases are increasingly being viewed as inflammatory disorders.²⁸ In the light of other work reporting an association between hostility and immune function, direct pathways linking hostility to lung function may involve influences on underlying chronic inflammatory processes. Such processes may be regulated through complicated immune phenomena in which many cells (such as neutrophils, eosinophils, and T lymphocytes) and associated cytokines play a role. For example, Miller and colleagues⁷ found increased natural killer cell numbers and cytotoxicity among hostile men than in less hostile men when engaged in marital conflict. Studies in patients with COPD have found a reduced CD4/CD8 ratio to be associated with lower levels of lung function and degree of airflow limitation.²⁹

Disturbances in neuroendocrine processes are related to both hostility and pulmonary function. Some evidence has linked hostility with increased sympathetic nervous system (SNS) activity as well as alterations in levels of cortisol or dysregulation of the hypothalamic-pituitary-adrenal (HPA) axis. For example, one study found that highly hostile men displayed more than twice the increase in cortisol excretion during daytime hours compared with less hostile men.³⁰ While it may seem paradoxical that activation of the HPA axis by psychological stress should be considered problematic (given that the release of cortisol has known anti-inflammatory effects), as discussed in more detail elsewhere we have come to understand that organisms need an optimal balance of neurohormones and neurotransmitters to maintain health.¹ Excessive SNS activity along with disturbances in HPA axis regulation (either hypo- or hyper-responsiveness) has also been linked to poorer pulmonary function.¹ In a laboratory study of acute stress reactivity and pulmonary function, individuals with and without asthma were challenged with speech and mathematical tasks. Increases in plasma epinephrine (adrenaline) and norepinephrine (noradrenaline) levels in response to the stress tasks were seen in both groups, accounting for 33–51% of the variance in concurrent pulmonary function.³¹

Alternatively, hostility may influence health through psychosocial pathways by its influence on social interactions and health damaging behaviors. For example, high levels of hostility often produce interpersonal conflict and hostility from others, leading to the withdrawal of social support.³² Numerous studies have linked social support to a broad array of health outcomes, with more recent work demonstrating links to relevant physiological parameters including cortisol expression.³³ Moreover, hostility has been consistently linked with increased likelihood of engaging in health damaging behaviors such as smoking or sedentary behaviour³⁴ which, in turn, may influence pulmonary function. Although physical activity is a potential confounder (or pathway) linking hostility with lung function, data on physical activity are not available for this sample so we could not examine this issue.

For more than 20 years, cigarette smoking has been recognised as the single most important risk factor for an accelerated rate of decline in pulmonary function in adult life.³⁵ Deleterious effects of cigarette smoking on lung function decline were evident, which raises the possibility of residual confounding by smoking in these analyses. Moreover, there was some indication that smokers were

more hostile. However, our analyses accounted for smoking in a variety of ways and, in almost all cases, hostility remained an independent predictor of rate of pulmonary function decline. This suggests that additional and perhaps more direct mechanisms linking hostility and pulmonary function need to be considered.

The findings of the present study are limited in that they pertain to older white men and thus cannot be generalised to women, non-white subjects, or younger populations. Other research has suggested that women have lower levels of hostility than men, and that black ethnic groups have higher levels of hostility than white subjects.³⁶ Research to date has suggested that hostility and lung health are similarly associated for both men and women, and for black and white subjects.¹⁷ However, further work is needed to ascertain more definitively whether the association between hostility and lung function can be generalised to other groups.

Identifying factors that predict a rapid decline in pulmonary function among older adults will increase opportunities for early intervention to protect lung health. This study provides prospective evidence that hostility is associated with a more rapid rate of decline in pulmonary function among older adult men, with effects strongest for FEV₁. Hypothesised mechanisms could include both direct effects on neuroendocrine and immune function as well as effects on health related behaviors. Previous research has suggested that hostility is not immutable, as a number of clinical trials have succeeded in altering (reducing) levels of hostility using psychosocial interventions.³⁷ Thus, the role of hostility in pulmonary health deserves a closer look.

LUNG ALERT

Asthma may protect against autoimmune diseases

▲ Tirosh A, Mandel D, Mimouni FB, et al. Autoimmune disease in asthma. *Ann Intern Med* 2006;144:877-83

In this cross sectional study, data from the Israeli Defence Force database were used to analyse the prevalence of autoimmune disorders in asthmatic and non-asthmatic military personnel between 1980 and 2003. Of the 488 841 individuals enrolled, significantly more women than men had autoimmune disorders. When comparing all autoimmune disorders together there was statistically significant evidence that autoimmune disorders were less prevalent in asthmatics across both sexes (prevalence 137.4/10 000 in non-asthmatics v 93.3/10 000 in asthmatics; risk ratio 1.48 (95% CI 1.33 to 1.64), $p < 0.001$). The study showed that there was a significantly lower prevalence of all autoimmune disorders except antiphospholipid syndrome in asthmatic women, and a lower prevalence of type 1 diabetes, vasculitis, and rheumatoid arthritis in asthmatic men than in their non-asthmatic counterparts. A follow up study tracing newly diagnosed autoimmune diseases showed varying incidence levels, generally lower in asthmatic subjects, depending on sex and type of autoimmune disorder.

This research suggests that asthma may affect the occurrence of autoimmune disorders depending on the disease and sex of the individual, with asthma generally being protective. The theory is that a T helper 2 weighted imbalance favours an allergic response that may protect against T helper 1 mediated autoimmune diseases.
